## **Chapter 4: Classification**

The linear model in Ch. 3 assumes the response variable Y is quantitiative. But in many situations, the response is categorical.

eg. eye color cancer diagnosis which movie I will watch rest

In this chapter we will look at approaches for predicting categorical responses, a process known as *classification*.

Classification problems occur often, perhaps even more so than regression problems. Some examples include

- 1. A person arrives at emergency room with a set of symptoms that could be a thibuted to one of three medical worditions. Which of the three conditions does the person have?
- 2. An online baubing service must be able to determine whether a transaction is fraudulant on the basis of user's 1P address, past transaction history, etc.
- 3. Something is in the street in fort of the self-driving an you are riding in. Is it a human or another car?

As with regression, in the classification setting we have a set of training observations  $(x_1, y_1), \ldots, (x_n, y_n)$  that we can use to "build a classifier". We want our classifier to perform well on the training data and also on data not used to fit the model (**test data**).

most importantly.

We will use the Default data set in the ISLR package for illustrative purposes. We are interested in predicting whether a person will default on their credit card payment on the basis of annual income and credit card balance.

" fit a modul

Yes or no => categorical.

## 1 Why not Linear Regression?

I have said that linear regression is not appropriate in the case of a categorical response. Why not?

Let's try it anyways. We could consider encoding the values of default in a quantitative repsonse variable Y

$$Y = egin{cases} 1 & ext{if default} \ 0 & ext{otherwise} \end{cases}$$

Using this coding, we could then fit a linear regression model to predict Y on the basis of **income** and **balance**. This implies an ordering on the outcome, not defaulting comes first before defaulting and insists the difference between these two outcomes is 1 unit. In practice, there is no reason for this to be true.

We could let  $Y = \begin{cases} 0 & \text{if default} \\ 1 & \text{otherwise} \end{cases}$ OR  $Y = \begin{cases} 1 & \text{if default} \\ 10 & \text{otherwise} \end{cases}$   $\begin{cases} 0/1 & \text{encodelary, but if has an advantage} \end{cases}$ 

Using the dummy encoding, we can get a rough estimate of P(default|X), but it is not guaranteed to be scaled correctly.

doesn't have to be between 0 and 1 but will provide an ordering.

Real problem : this comment be easily extended to more than 2 classics. We can instead use methods specifically fimulated for categorical or sponges.

## 2 Logistic Regression

Let's consider again the default variable which takes values Yes or No. Rather than modeling the response directly, logistic regression models the *probability* that Y belongs to a particular category.

For any given value of balance, a prediction can be made for default.

### 2.1 The Model

How should we model the relationship between p(X) = P(Y = 1|X) and X? We could use a linear regression model to represent those probabilities

standard logistic function  $f(x) = \frac{e^{x}}{1 + e^{2x}}$ 

2.1 The Model

To avoid this, we must model p(X) using a function that gives outputs between 0 and 1 for all values of X. Many functions meet this description, but in *logistic* regression, we use the *logistic* function,

$$p(x) = \frac{e^{B_0 + \beta x}}{1 + e^{B_0 + \beta x}}$$

After a bit of manipulation,

$$\frac{p(x)}{1-p(x)} = \frac{e^{\beta_0 + \beta_1 x}}{1/[+e^{\beta_0 + \beta_1 x}]} = e^{\beta_0 + \beta_1 x}$$

$$= e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} = \frac{e^{\beta_0 + \beta_1 x}}{1/[+e^{\beta_0 + \beta_1 x}]} = e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

$$\int \frac{1}{1-p(x)} e^{\beta_0 + \beta_1 x} e^{\beta_0 + \beta_1 x}$$

eq. 
$$p(x) = 0.2 \implies odds = \frac{0.2}{1-0.2} = \frac{1}{4}$$
 "one in 5 people default"

By taking the logarithm of both sides we see,

$$\log\left(\frac{p(x)}{1-p(x)}\right) = \beta_0 + \beta_1 x$$

$$(\log - 0 d d s'')$$

Recall from Ch. 3 that  $\beta_1$  gives the "average change in Y associated with a one unit increase in X." In contrast, in a logistic model,

increasing 
$$X$$
 by one unit corresponds the changing the log-odds by  $\beta_r$   
 $\Longrightarrow$   
Increasing  $X$  by one unit corresponds the multiplying the odds by  $e^{\beta_r}$ 

However, because the relationship between p(X) and X is not linear,  $\beta_1$  does **not** correspond to the change in p(X) associated with a one unit increase in X. The amount that p(X) changes due to a 1 unit increase in X depends on the current value of X.

Regardless of the Value of X,  
IF B1 is positive => increasing X increases 
$$p(X)$$
  
IF B1 is negative => increasing X decreases  $p(X)$ .

#### 2.2 Estimating the Coefficients

The coefficients  $\beta_0$  and  $\beta_1$  are unknown and must be estimated based on the available training data. To find estimates, we will use the method of *maximum likelihood*.

The basic intuition is that we seek estimates for  $\beta_0$  and  $\beta_1$  such that the predicted probability  $\hat{p}(x_i)$  of default for each individual corresponds as closely as possible to the individual's observed default status.

```
l(\beta_{o},\beta_{i}) = T p(x_{i}) T (1 - p(x_{i}))
   to do this, use the likelihood function
                                                 1: 31=1
                                                          7:4:1=0

```

7

### **2.3 Predictions**

Once the coefficients have been estimated, it is a simple matter to compute the probability of default for any given credit card balance. For example, we predict that the default probability for an individual with balance of \$1,000 is

$$\hat{\gamma}(x) = \frac{e^{\hat{B}_0 + \hat{\beta}_1 x}}{1 + e^{\hat{B}_0 + \hat{\beta}_1 x}}$$

$$\hat{\gamma}(1000) = \frac{e^{10.6513 + 0.0055 \times 1000}}{1 + e^{10.6513 + 0.0055 \times 1000}} = 0.00576$$

In contrast, the predicted probability of default for an individual with a balance of 2,000 is

$$\hat{p}(2000) = \frac{\underbrace{-10.6513 + 0.0055 \times 2000}_{l + \overline{c}^{10.6513 + 0.0055 \times 2000}} = 0.586$$

58.6% > 50% => might predict default = YES if preshold = 0.5.

#### 2.4 Multiple Logistic Regression

We now consider the problem of predicting a binary response using multiple predictors. By analogy with the extension from simple to multiple linear regression,

Just as before, we can use maximum likelihood to estimate  $\beta_0, \beta_1, \ldots, \beta_p$ .

Bstrugent (Yes) <0 => If you are a student, UESS likely to default holding balance & income constant.
 studet confounded w/ balance ( if you are a student you more likely to have higher balance)
```

```
but if you have the same balance (and inome) as non-student, less likely to default.
```

By substituting estimates for the regression coefficients from the model summary, we can make predictions. For example, a student with a credit card balance of \$1,500 and an income of \$40,000 has an estimated probability of default of

$$p(x) = \frac{e^{-10.869 + 0.00574 \times 1500 + 0.00003 \times 40.000 - 0.6468 \times 1}}{1 + e^{-10.869 + 0.00574 \times 1500 + 0.00003 \times 40.000 - 0.6468 \times 1}}$$

$$= 0.058$$

A non-student with the same balance and income has an estimated probability of default of

$$\frac{i}{p(x)} = \frac{e^{10.869 + 0.00574 \times 1500 + 0.000003 \times 40000 - 0.6468 \times 0}}{1 + e^{10.869 + 0.00574 \times 1500 + 0.000003 \times 40000 - 0.6468 \times 0}}$$
predivt/auguret u/ = 0.105

### **2.5 Logistic Regression for** > 2 Classes

We sometimes which to classify a response variable that has more than two classes. There are multi-class extensions to logistic regression ("multinomial regression"), but there are far more popular methods of performing this.

## 3 LDA "linear discriminant analysis"

Logistic regression involves direction modeling P(Y = k | X = x) using the logistic function for the case of two response classes. We now consider a less direct approach.

#### Idea:

Model the distribution of the predictors separately in each response class (given Y) and then use <u>Bayes theorem</u> Tr flip truse and get estimates P(Y = k | X = x) $\downarrow P(A|B) = \frac{P(B|A)P(A)}{P(B)}$ 

Why do we need another method when we have logistic regression?

- 1. We might have more than 2 response classes.
- 2. When the classes are well-separated, the parameter estimates for logistic repressil are suprisingly unstable.

3. In n is small and the distributions of the predictors X NN in each class, LDA is more stable than logistic regression.

#### **3.1 Bayes' Theorem for Classification**

Suppose we wish to classify an observation into one of K classes, where  $K \ge 2$ . Codegorial  $\gamma$  can take K possible distinct and unordered values.

 $\pi_k$  - oreall probability that a randomly chosen observation comes from k<sup>th</sup> class. "prior probability"

$$f_{k}(x) = P(X = x | Y = k) \quad \text{Idisorte } X)$$

$$= \frac{1}{Probability Het X falls in a small region around X given Y = k \quad (\text{continuous } X).$$

$$\int_{a}^{a} \frac{1}{density function''} t_{b} X \quad \text{for an observation that corres from class } k$$

$$\frac{1}{V} \frac{1}{V(k) \log d^{\mu}} = \frac{1}{V(x)} \frac{P(x = x) + P(y = k)}{P(x = x)} + \frac{1}{V(x)} \frac{P(x = x)}{P(x = x)} \quad (Bayes theorem).$$

We will use the same abbreviction as before  $p_k(x) \leftarrow$  "posterior probability" that an obs w/X = x comes from class In general, estimating  $\pi_k$  is easy if we have a random sample of Y's from the population.

Compute the fraction of training observations that come from kth class.

Estimating  $f_k(x)$  is more difficult unless we assume some particular forms.

If we can estimate  $F_{k}(x)$  we can develop a classifier that is close to the "best" classifier (more later).

Notation

assignment tu class w/ highest prc(x) is culled "Bayes classifier" and is known to and is known to be notimal i.e.

be optimal i've. we con do no better.

#### 3.2 p = 1

Let's (for now) assume we only have 1 predictor. We would like to obtain an estimate for  $f_k(x)$  that we can plug into our formula to estimate  $p_k(x)$ . We will then classify an observation to the class for which  $\hat{p}_k(x)$  is greatest.  $L = \Pi_{K} f_{K}(x)$ 

estimating the Bayes classifier !  $\overline{\Sigma_{j=1}^{k}} \pi_{j} f_{j}(x)$ Suppose we assume that  $f_{k}(x)$  is normal. In the one-dimensional setting, the normal density takes the form Gaussian

JP=1

$$\mathcal{F}_{k}(\boldsymbol{x}) = \frac{1}{\sqrt{2\pi}\boldsymbol{\varepsilon}_{k}^{2}} \boldsymbol{\varepsilon}_{k} \left( -\frac{1}{2\boldsymbol{\varepsilon}_{k}^{2}} \left( \boldsymbol{x} - \boldsymbol{\mu}_{k} \right)^{2} \right)$$

Mk and S' mean and variance parameters for kth class. Let's also (for nou) assume  $\delta_1^2 = \dots = \delta_k^2 = \delta_1^2$  (shared variance term).

Plugging this into our formula to estimate  $p_k(x)$ ,

$$p_{K}(x) = \frac{\prod_{k=1}^{K} e_{x} p\left(-\frac{1}{26^{2}} (x - \mu_{k})^{2}\right)}{\sum_{\ell=1}^{K} \prod_{k=1}^{L} \frac{1}{52\pi 6^{2}} e_{x} p\left(-\frac{1}{26^{2}} (x - \mu_{k})^{2}\right)}{\sum_{\ell=1}^{K} e_{x} p\left(-\frac{1}{26^{2}} (x - \mu_{k})^{2}\right)}$$

We then assign an observation X = x to the class which makes  $p_k(x)$  the largest. This is equivalent to

(log + rearranging)  
assign obs. to class for which  
$$\overline{J}_{k}(x) = 2C \frac{\mu_{k}}{6^{2}} - \frac{\mu_{k}^{2}}{26^{2}} + \log(\Pi_{k})$$

is maximized.

.

**Example 3.1** Let K = 2 and  $\pi_1 = \pi_2$ . When does the Bayes classifier assign an observation to class 1?

When 
$$\delta_1(x) > \delta_2(x)$$
  
 $\approx \frac{M_1}{2} - \frac{M_1^2}{26^2} + \log(\Pi_1) > x \frac{M_2}{6^2} - \frac{M_2^2}{26^2} + \log(\Pi_2)$   
 $\chi M_1 - \frac{M_1^2}{2} > \chi M_2 - \frac{M_2^2}{2}$   
 $\lambda \chi (M_1 - M_2) > M_1^2 - M_2^2$   
 $\chi > \frac{M_1 + M_2}{2}$  decision boundary

Bayes classifier

In practice, even if we are certain of our assumption that X is drawn from a Gaussian distribution within each class, we still have to estimate the parameters  $\mu_1, \ldots, \mu_K, \pi_1, \ldots, \pi_K, \sigma^2$ . to estimate the Dayes class for.

The *linear discriminant analysis* (LDA) method approximated the Bayes classifier by plugging estimates in for  $\pi_k, \mu_k, \sigma^2$ .

$$\hat{\mu}_{k} = \frac{1}{n_{k}} \sum_{\substack{i:y_{i}=k}}^{\infty} x_{i} \qquad \text{average of training obs in kth class}$$

$$\hat{\mu}_{k} = \frac{1}{n_{k}} \sum_{\substack{k=1 \\ k=1}}^{k} \sum_{\substack{i:y_{i}=k}}^{\infty} (x_{i} - \hat{\mu}_{k})^{2} \qquad \text{weighted average of class variances.}$$

$$n = \# \text{ training obs.}$$

$$n_{k} = \# \text{ training obs in class k}$$

$$from \text{ scinitify provided get}$$

Sometimes we have knowledge of class membership probabilities  $\pi_1, \ldots, \pi_K$  that can be used directly. If we do not, LDA estimates  $\pi_k$  using the proportion of training observations that belong to the *k*th class.

$$\hat{\Pi}_{k} = \frac{n_{k}}{n}$$

The LDA classifier assignes an observation X = x to the class with the highest value of

$$\int_{K} (x) = x \frac{\hat{\mu}_{K}}{\hat{\sigma}^{2}} - \frac{\hat{\mu}_{k}}{2\hat{\sigma}^{2}} + \log(\hat{\pi}_{k}).$$

The LDA test error rate is approximately 12.22% while the Bayes classifier error rate is approximately 10.52%. % # act Weeks 10.34 + 3855

$$\frac{1}{44} \text{ lest data points} = \frac{10000}{40000} = 12.22\%$$

The Bayes error rate is the best we can possibly do! (we can only estimate it because this is a simulated example).

The LDA approach did almost as well. The LDA classifier results from assuming that the observations within each class come from a normal distribution with a class-specific mean vector and a common variance  $\sigma^2$ and plugging estimates for these parameters into the Bayes classifier.

> we will relax this later.

### 3.3 p > 1

We now extend the LDA classifier to the case of multiple predictors. We will assume

 $X = (X_{1}, ..., X_{p}) \text{ drawn from a multivariate Gaussian den W class specific preen vector 's common counsince$ between component follows Gaussian and some covariance $<math display="block">V_{p(X_{1}, Z_{2})}^{p(X_{1}, Z_{2})} \Rightarrow EX = \mu$  Cov(X) = Z

Formally the multivariate Gaussian density is defined as

```
In the case of p > 1 predictors, the LDA classifier assumes the observations in the kth
class are drawn from a multivariate Gaussian distribution N(\mu_k, \Sigma). Common counter matrix.
Plugging in the density function for the kth class, results in a Bayes classifier
  assign an observation X=x the class for which
      discriminant fundion -> \delta_{k}(\underline{x}) = \underline{x}^{T} \underline{\Sigma}' \underline{\mu}_{k} - \frac{1}{2} \underline{\mu}_{k}^{T} \underline{\Sigma}' \underline{\mu}_{k} + \log T_{k} is maximized.
Once again, we need to estimate the unknown parameters \mu_1, \ldots, \mu_K, \pi_1, \ldots, \pi_K, \Sigma.
      as p=1.
Use similar ideas the estimate.
To classify a new value X = x, LDA plugs in estimates into \delta_k(x) and chooses the class
                                                                  \Rightarrow \hat{\delta}_{k}(\Xi) and choose K which maximizes it
(i.e. estimating Bayes dassition)
which maximized this value.

                                      81
           Why does the LDA classifier do such a poor job of classifying the customers who default?
               Only 3.33% of individuals in training data sot defaulted.
                A simple (but usaluss) classifier could just predict default = No and only get 3.33% wrong!
               LDA is trying the approximate the Bayes classifier => yield smallest possible oreall and rate.
                A CC carpony may want micclassifying default = Yes people, can adjust how we classify.

### 3.4 QDA

LDA assumes that the observations within each class are drawn from a multivariate Gaussian distribution with a class-specific mean vector and a common covariance matrix across all K classes.

*Quadratic Discriminant Analysis* (QDA) also assumes the observations within each class are drawn from a multivariate Gaussian distribution with a class-specific mean vector but now each class has its own covariance matrix.

Under this assumption, the Bayes classifier assigns observation X = x to class k for whichever k maximizes

When would we prefer QDA over LDA?

## 4 KNN

Another method we can use to estimate P(Y = k | X = x) (and thus estimate the Bayes classifier) is through the use of K-nearest neighbors.

The KNN classifier first identifies the K points in the training data that are closest to the test data point X = x, called  $\mathcal{N}(x)$ .

Just as with regression tasks, the choice of K (neighborhood size) has a drastic effect on the KNN classifier obtained.
